As seen in the heap theoretical analysis and based off the data above, it outperforms the array implementation. This is because of the way that pop_min functions. In the heap it has a O(log N) where the array has a O(N). This change makes the heap implementation effectively better for larger data sets. However, with smaller data sets you can see that when the density is held to 1, the number of edges has little effect on runtime between the implementations. This is because the edges are similar between both implementations.
